Changes in the unemployment in Croatia are largely permanent. However, transitory movements account for most of the unemployment dynamics after 2008. Unemployment series is non-stationary but mean-reversing, non-linear with structural breaks and significant white and red-noise in the data. This paper estimates Multivariate singular spectrum model (MSSA) to explain overall fluctuations in unemployment registered during 1998–2013. Unemployment behaviour in Croatia shows evidence of cyclo-stationarity caused by seasonal employment effects. We use 88 time series (variable) to explain observed fluctuations with our MSSA model explaining 76 % of the total unemployment variance comprehensively. Evidence of this study demonstrates that unemployment phenomena should be modelled by using a non-linear model with multivariate singular spectrum models giving more robust and empirically valid results in relation to standard modelling techniques. A 5–6 years limit cycle for unemployment is isolated dominating unemployment behaviour in Croatia over the last two decades!

Keywords: Multivariate Singular Spectrum Analysis, Unemployment, Non-Linear, Persistence, Causality, Croatian Disease, Partial Hysteresis, Spectral Methods.

Introduction

This paper is the first to explore unemployment nature and determinants in Croatia in a comprehensive way (88 time series/variables analysed) and using non-linear multivariate singular spectrum modelling. Empirical findings from the study both contribute significantly to the body of literature on unemployment in Croatia and offer valuable practical knowledge to policy makers to address one of the biggest issues Croatian economy has been facing over 24 years. Unemployment causes persistent and pronounced adverse effects on the economy. Economic policy designed to address the issue of unemployment is often inadequate and inefficient. To deal efficiently with unemployment, one must know the true nature of unemployment, i.e. what causes unemployment and its determinants behind. Without this empirical knowledge, policy makers design economic policies having adverse effects on the economy. The biggest issue from the last economic crisis is sluggish fall of unemployment despite the economy's slow recovery. This raises several questions on the nature of unemployment such as: Is unemployment following a random walk (Hysteresis theory) or natural rate of unemployment? What drives natural rate of unemployment rise and are cyclical or structural components of unemployment responsible?

conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of Croatian Science Foundation.

Unemployment has hit hard transition economies. A hit has been particularly hard for the Croatian economy with unemployment rates among the highest in the EU making unemployment the biggest issue for Croatia right now. The economy is still falling with stagnating unemployment mostly because of the favourable seasonal effect coming from the tourism industry. Several constraints do arise when investigate the nature and determinants unemployment in Croatia. Short time series and noisy data are at the top followed by stationarity (Furuoka, 2014) and non-linearity. Our study results show that unemployment in Croatia is non-stationary and non-linear with a long memory and adverse effects lasting in the long run. Empirical results of this study point to the possibility that unemployment in Croatia is a cyclo-stationary process because of strong seasonal effects spreading from the tourism industry. With a time series with such statistical characteristics, appropriate empirical modelling is not an easy task. Previous studies in Croatia on unemployment followed the premise of that unemployment is either I(0) or I(1). Investigations in earlier articles show unemployment in Croatia is neither I(0) nor I(1) but fractionally integrated (Skare & Stjepanovic, 2013). In fact, unemployment is non-stationary and means reverting but mean reversion acts in the very long run (long range dependence or long memory). We find evidence also unemployment having dual long memory - both in the

¹ This work has been fully supported by the Croatian Science Foundation under the project number 9481 Modelling Economic Growth - Advanced Sequencing and Forecasting Algorithm. Any opinions, findings, and

conditional mean and conditional variance. All evidence points to a single conclusion – unemployment in Croatia is a process with complex behaviour having long-lasting, although not permanent effects. This finding is rather important, and it is not falling within standard theory notion of unemployment being transitory or permanent in nature. From this notion itself, i.e. unemployment having permanent or transitory behaviour, policy makers design what they think is the appropriate policy action. For example, if unemployment in Croatia is transitory, monetary and fiscal policy in place now is acting pro-cyclically. Our study results offer strong empirical evidence to resolve this issue.

In fact, factors behind unemployment dynamics in Croatia are both structural and cyclical in nature. Unemployment has long lasting but not permanent effects on the economy with unemployment negative impact lasting over 20 years before reverting to the natural unemployment rate. This means that active monetary and fiscal policy is needed to restore the initial equilibrium level. No policy action is also an option, but, in that case, negative effects of the unemployment will keep pounding the economy over 20 years. Another critical empirical finding of this study is the cyclical nature of unemployment. Unemployment in Croatia exhibits quite remarkably precise 5-6 years business cycles recurring timely. This is indeed very important since a theory of unemployment having cyclical behaviour has been widely ignored. Unemployment in Croatia is indeed cyclical in nature following a 5-6 years cycle having five such episodes in the last 24 years. Our model suggests that unemployment in Croatia us settling down (stagnating) and the current cycle is showing signs of its end. This cyclical behaviour of unemployment is both important from theoretical and practical point of view. If empirical results of this paper are validated by other studies and researchers, then a 'partial Hysteresis' hypothesis should be recognized with unemployment since both Hysteresis and the natural rate of unemployment hypothesis in Croatia are true. Both Hysteresis and the natural rate of unemployment govern unemployment dynamics in Croatia causing cyclical behaviour and observed 5-6 years cycles.

A new issue is the possible negative effect of Croatian disease², i.e. cyclo-stationarity in unemployment caused by strong seasonal effects in the tourism industry. In the short run, seasonal unemployment effects can alleviate high unemployment issue but in the long run it can be rather a cause of high unemployment and not the solution (possible de-industrialization, jobless growth, net employment change threshold effect).

This paper seeks to encourage further research on phenomena of unemployment in Croatia, in particular, nonlinear studies and studies addressing Hysteresis and the natural rate of unemployment issues. This means that cyclical unemployment behaviour is not essentially linked only to economic cycles, but a part of its cyclical behaviour is caused by its permanent/transitory components (Hysteresis and the natural rate of unemployment dynamics).

This study extends previous research of both theory and methodology on unemployment in Croatia. Earlier studies

do not address the long memory issues in the unemployment or 'partial Hysteresis'. This is not the case only for the existing literature on unemployment in Croatia. To the best of our knowledge, only a few papers explore unemployment dynamics using singular spectrum analysis and possibly none in Croatia.

The paper is structured as follows. While section 2 provides a literature review on different unemployment theories; the methodology of the paper is described in section 3. Section 4 offer analysis and empirical findings of the paper by using MSSA modelling with concluding remarks and discussion on the findings in the section 5.

Theories of Unemployment Fluctuations – Literature Review

In this section, we provide a review only of those studies that are closely connected to the subject of this paper and that of the studies investigating unemployment in Croatia. The Hysteresis issue has been thoroughly addressed by (Blanchard et al., 1987; Jaeger & Parkinson, 1994). Empirical findings are mixed with unemployment time series having random walk properties and others fractional integration with Hysteresis remaining an open discussion. Unemployment dynamics has often been linked to the natural rate of unemployment and its transitory/permanent behaviour. Well known are the studies on the subject by (Blanchard et al., 1986, 1996; Sargent, 1973; Juhn et al., 1991; Staiger et al., 1997; Stiglitz, 1997; Friedman, 1968; Phelps, 1998; 1968; 1967; 1994). Different views on the theory of the natural rate of unemployment are known in the body of economic literature but the unique equilibrium value of unemployment can hardly be observed if we do not possess sufficeint quantitative knowledge on the natural rate permanent/transitory components. A known non-linear long memory model for the US unemployment developed by van (Dijk et al., 2002) shows non-linear modelling that outperforms the related standard various models in fitting unemployment. Fractionally integrated approach to the subject of long memory unemployment has been extensively covered by (Gil-Alana, 2003; Caporale, 2008; 2007; 2009).

The possibility of fractional integration macroeconomic variables for Croatia is studied in (Skare & Stjepanovic, 2013). Studies on unemployment in Croatia investigate labour market mismatch as in (Tomic & Domadenik, 2012; Tomic, 2014; Obadic, 2006), long-term unemployment Botric, 2009) and labour market differences (Botric, 2004). Unemployment determinants in Croatia have been investigated in (Skare, 2001) and structural unemployment in (Botric, 2011). The impact of regional differences on self-employment in Croatia is analysed in (Botric, 2012). The active labour market policy impact has been investigated in (Babic, 2003) and labour market structure in (Rutkowski, 2003). The impact of education on the labour market and long run unemployment consequences have been thoroughly investigated in (Bejakovic, 2003; 2006). Empirical econometric papers

dealing with fractional integration and non-linearity in the unemployment series in Croatia as well empirical econometrics paper are missing and one close to the issue we address here can be found on natural rate of unemployment in Croatia is (Sergo *et al.*, 2009). Inflation – unemployment relationship in the Phillips curve framework for Croatia is studied in (Sergo *et al.*, 2012). (Blazevic, 2013) studies the impact of minimum wages on employment in Croatia finding weak evidence to support the trade-off hypothesis.

Data and Multivariate Singular Spectrum Analysis Methodology

In this paper, we construct a set of a large database including 88 time series variables (see table A1) covering the monthly data from 1990 to 2013. Data were collected from the Croatian national bank online and published databases, IFS financial statistics, Croatian statistical office online and published databases covering the period 1990–2013. Because of the monthly data constraints, instead of using GDP we use the index of industrial production facing the problem of missing data in the time series. To resolve the problem of missing data (particularly from 1990-1992 and 1998-2000), we reconstruct data using SSA Reconstruction/ Prediction filter (Kspectra program 3,4) following (Harvey 1990; Hamilton, 1994; Priestley 1981). Time series data (variables) used in this study are listed in the appendix (see table A1). Following standard multivariate singular spectrum analysis procedure to identify statistically relevant oscillations and limit cycles, from a set of 88 time series 21 time series (variables) were selected backed by data availability, theoretical prior research (theory) and the preprocessing analysis (PCA-MSSA screening) as limit cycle (oscillations) candidate for the MSSA study of unemployment dynamics in Croatia over 1990–2013 time period.

Spectral Analysis Techniques

Spectral techniques are used in this study to analyse, explain and capture the unemployment trajectory in Croatia over the observed period. Since too many missing data were for the sample from 1990–2013 we decide to use a sample with only a few missing data in the time series, i.e. monthly data sample from 1998-2013. The spectral analysis technique is used to decompose unemployment series into different frequency band paths over the phase space. Capturing different frequency bands spectrum overall variance in the unemployment behaviour the nature of unemployment can be explained, and unemployment primary sources and determinants isolated. The evaluated spectrum shows periodicity and large oscillations in the unemployment series behaviour over the sample. In this paper, we use Squared Coherency (same as R2 in a linear time domain).

Choice of Modelling Techniques

Coherency measure captures the proportion of the variance in the unemployment in a given frequency point explicated by the variance in the 88 selected individual time series (variables). Standard spectral analysis models usually

refer to coherency spectrum as the R2 exposing the proportion of variance in unemployment that can be explicated by the variance in another individual time series (bivariate spectral analysis). The rule of thumb is to considerate coherence measure around 0.50 is moderate and >0.75 as statistically significant. Empirical results from the coherency analysis were used to select potential candidates for the MSSA model from a set of 88 time series. Results of the coherency spectrum analysis due to space constraint are not presented here.

Building an MSSA of unemployment for Croatia involves: decomposition and reconstruction. Decomposition is carried by embedding the original time series (88) into lagged vector sequences of the form (trajectory matrix) following (Golyandina *et al.*, 2013; Ghil *et al.*, 1997; 2002; 1996; Kimoto & Ghil, 1993).

Original unemployment series is first decomposed into reconstructed series, to isolate the trend, periodic components and oscillatory components. SSA is extended to the multivariate singular spectrum (multivariate input channels – time series/variables) analysis of unemployment to get more robust empirical results due to unemployment complex behaviour failed to capture with singular spectrum analysis.

To test for the statistical significance of the identified oscillatory channels (extracted spectral components) we use a Monte Carlo test (MC-SSA) (Allen *et al.*, 1996) against red noise null hypothesis following AR(1). (For more details see (Ghil *et al.*, 1996; 1997; 2002).

We also check the robustness of MSSA results (statistical significance of isolated oscillations), with a comprehensive causality test based on singular spectrum analysis following (Hassani *et al.*, 2010).

Granger causality test (based on SSA) takes the form

$$F_{X|Y}^{(h,d)} = \frac{\Delta_{X_{K+H_x}|Y_{K+H_y}}}{\Delta_{X_{K+H_x}}}$$
(1)

where $\Delta_{X_{K+H_x}} \equiv \mathcal{L}(X_{K+H_x} - \hat{X}_{K+H_x})$ representing mean square forecast error from univariate SSA, $\Delta_{X_{K+H_x}|Y_{K+H_y}} \equiv \mathcal{L}(X_{K+H_x} - \tilde{X}_{K+H_x})$ having XT and YT+1 (lagged differenced series) being a mean square forecast error from MSSA. The rule of thumb is $F_{X/Y}^{(h,d)} < 1$, YT+1 Granger cause (better forecast) XT and if $F_{X/Y}^{(h,d)} > 1$ no association between XT and YT+1 exists. A bivariate Granger causality (forecasting feedback) exists if both $F_{X/Y}^{(h,d)} < 1$ and $F_{Y/X}^{(h,d)} < 1$. To check forecasting statistical significance between SSA and MSSA forecasting techniques, Mariano and (Diebold, 1995) test of the form

$$S = \overline{D} \sqrt{\frac{n+1-2h+h(h-1)/n}{n \operatorname{var}(\overline{D})}}$$
 (2)

following (Hassani *et al.*, 2010) with (\overline{D}) being the sample mean of the vector Dt and $\widehat{\text{var}}(\overline{D})$ autocovariance of Dt is performed.

Methodological Issues

Developing a MSSA model for unemployment in Croatia demands that several methodological issues are addressed to deal efficiently the problem of oscillation-like fluctuations and noisy observation (background) noise. Few major issues are briefly considered here.

Groth *et al.*, (2011) forward the problem of poor oscillation pattern identification under the condition of corresponding Eigen values similar in size. VARIMAX rotation for MSSA algorithm is used to address this issue. For further discussion on VARIMAX procedure (Groth & Ghil, 2011).

The number of observations (n) for all series n = 192 satisfying (Granger & Hatanaka, 1964) conditions for minimum n. All data are seasonally adjusted following Census X-13 ARIMA, detrended using (Hodrick & Prescott, 1997) and non-dimensionalized by dividing HP residuals with HP trend. To make comparison and impulse response analysis more flexible, all time series were divided by their standard deviations (normalised). Following (Granger & Hatanaka, 1964; Elsner & Tonis, 1996; Golyandina *et al.*, 2010) an optimal window length (temporal lag) was chosen considering a general rule m = Nt/2, Nt/3, Nt/4. Maximum m = 96 lag was selected and has been used in the analysis for Monte Carlo tests (1000 noise realisations) to trace statistically significant deterministic behaviour.

Spectral Decomposition of Unemployment – Empirical Results

This section explains the results of the univariate SSA and multivariate MSSA spectral decomposition of unemployment in Croatia over 1990–2013. As expected, unemployment time series show a high level of persistence and long memory in the Granger (1966) sense. Trend component in the series is strong, with four SSA components explaining almost 92 % of the variance in the unemployment series.

Deviations of the original unemployment series from SSA trend reconstructed show the impact of transitory shocks resulting from within and outside Croatian economy. First significant deviation (0-50 months) is a consequence of the war condition during 1990-1995. A substantial deviation from the trend occurred after the VAT introduction in 1998. Sharp deviation from the trend repapered in 2005 with continuous deepening after the crisis of 2008. The reconstructed trend shows evidence of high persistence in the unemployment series. Evidence is that shocks (cyclical effects) have a strong and persistent (long lasting) impact on the unemployment dynamics in Croatia. The structural break in the unemployment series resulting from the VAT introduction in 1998 was long lasting with shocks in the unemployment disappearing only after three years (mean reversion). Fiscal austerity policies in place after 2009 have a large impact on the unemployment dynamics. Because of the fiscal austerity measures, unemployment in Croatia has significantly shifted from its trend showing no sign of mean reversion soon. Seasonal effect on the unemployment is also present having persistent effects on the unemployment dynamics. During 1995–1998, unemployment had had a trend-in-mean dynamics with cyclical and seasonal effects being neutral to the movements on the labour market. This condition drastically changes after the VAT introduction and after being driven by public debt expansion. The crisis of 2008 completely changed the deficit spending policy resulting in sharp trend deviation in the unemployment series. Unemployment in Croatia during 1990's was mainly a consequence of structural changes in the economy (structural factors) with cyclical factors (shocks) dominating unemployment after 2005. Technology and sectoral shifts, diminishing importance of industry and rising service sector's (tourism) share in aggregate output tightened-up unemployment. This in turn unemployment much more vulnerable to the seasonal and cyclical effects than ever before in history. Unemployment from structural phenomenon in 1990's shifted to the seasonal/cyclical phenomenon in the 2000's.

Multivariate (MSSA) Model of Unemployment

Previous section shows spectral decomposition for the unemployment series in Croatia using univariate SSA (unemployment time series alone) identifying statistically relevant oscillations between 12 and 20-month cycles. Since unemployment as a phenomena is a complex one, to study its true nature, another time series (that of aggregates) must also be addressed. This means that standard univariate SSA decomposition of the previous section should be extended to include several other time series variables (aggregates) that are expected to offer an explanation for the oscillations in the unemployment dynamics. In order to do that, multivariate SSA (MSSA) decomposition is used here. Using time series data for other 87 variables (see table A1), i.e. multichannel time series an MSSA model is used to study oscillations and co-movements between unemployment and various variables (time series). To detect important oscillations in the unemployment dynamics (Eigen value pairs), multichannel singular spectrum analysis (reduced covariance) of the unemployment series is applied. Results of the MSSA analysis are shown in figure 1.

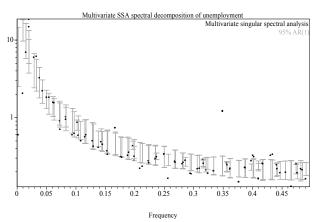

Figure 1. Multivariate Singular Spectrum Analysis of Unemployment Source: Author's calculation

Figure 1 show several signals (variables) that are possible candidates to explain the oscillatory behaviour of the unemployment series. Eigen value pairs that do not fall in the 95 % Monte Carlo error band (from 1000 surrogate series), i.e. that are outside error band, pass the test as

statistically significant oscillations. The red noise hypothesis (oscillations being background red noise) is rejected for Eigen value pairs (EOF's) 1-16, 19-20, 38-41, 43-47. To check that identified Eigen value pairs are statistically significant we check their phase dynamics (phase quadrature). Since the identified Eigen value pairs meet the phase quadrature test (not displayed here), there is indeed a statistically significant relation between unemployment and identified oscillatory components. The relation between unemployment dynamics and identified MSSA components (time series oscillators) is not a consequence of random shocks but related co-movements in the phase space (phase difference). Identified time series (statistically significant at 5 % significance level) related to the shocks in the unemployment dynamics, i.e. oscillatory components related to changes in unemployment dynamics are:

- Industrial production (energy) AE;
- Industrial production (intermediate goods) AI;
- Industrial production (capital goods) BB;
- Industrial production (durable consumer goods)
 CD;
- Industrial production (non-durable consumer goods) CN;
- Indices of stock (energy) AES;
- Indices of stock (intermediate goods) AIS
- Indices of stock (capital goods) BBS;
- Indices of stock (durable consumer goods) CDS;
- Indices of stock (non-durable consumer goods) CNS;
- Croatian disease (share of employment in tourism in total employment) CD's(CD01);
- Croatian national bank (international reserves)
 CBR;
- Core inflation CIP;
- Consumer price index CPI;
- Budget/surplus deficit BP;
- CNB discount rate DR;
- Industrial production (total industry Euro area 18 countries) EU;
- New entrants to the register 4 (or more)-year vocational secondary school and grammar school NER4:
- Loans to businesses (% share in total credits) CTE;
- New entrants to unemployment (first-time job seekers) NERFT;
- Nominal net wage NNW.

Identified statistically significant oscillatory components (time series) explain 75,98 % of the total variance in the unemployment dynamics in Croatia over the 1998–2013 period. Therefore, changes (shocks) in this time series can explain most of the changes in the unemployment dynamics that is visible from the figure 2.

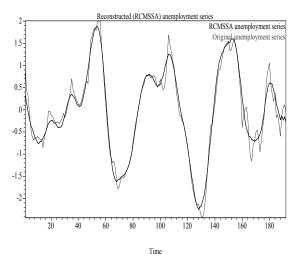

Figure 2. Original and MSSA reconstructed unemployment series 1998–2013

Source: Author's calculation

Reconstructed unemployment series (black) using identified MSSA components (multivariate time series) fit the original unemployment series (grey) quite well. This is not surprising at all since changes identified multivariate components explain almost 76 % of the total variance in the unemployment dynamics. Consequently, we can conclude that unemployment changes in Croatia during 1998–2013 can well be explained by movements (shocks) in identified 21 time series (multivariate components). Unemployment persistence (hysteresis) accounts for the most of the change in unemployment dynamics (18,92 %). Multivariate SSA spectral decomposition of statistically significant time series components (oscillations) is visible from the table 1.

Source: Author's calculation

When compared to the natural rate of unemployment series, we can conclude that hysteresis hypothesis is, in fact, true for Croatia. There is a large gap between actual unemployment and the natural rate of unemployment dynamics. Consequently, unemployment in Croatia is not following or converging to the natural unemployment path and show no sign of mean reversion. Under such conditions, an active economic policy is required since new equilibrium on the labour market can be reached only under high unemployment levels. At this point, unemployment becomes a significant issue in the long run with negative effects on the unemployment dragging economy and production down.

Industrial production (energy) accounts for 15,46 % of the total variance in the unemployment dynamics. Businesses in Croatia on an average spend about 60 % of their annual expenses on costs of goods and services and repeated change in the cost of energy have adverse effects on their business position on the market. When compared to the competition, firms in Croatia face much larger energy costs and low energy efficiency. After the start of 2008 crisis, electricity and natural gas prices increased significantly. This has caused adverse effects for a business that cut hiring resulting in job creation rate drop. Large fluctuations in the energy prices on industry after 2008 had a large negative impact on unemployment dynamics in Croatia.

Spectral Granger Causality Analysis of Unemployment

In this section spectral Granger causality is performed on the MSSA components (series) that we have identified previously as statistically significant and having an impact on unemployment dynamics. Granger causality results (see Table 2) confirm the results obtained from the MSSA analysis. Identified limit cycles (oscillatory pairs) thus in Granger sense have a significant impact on the unemployment trajectory path. Residual forecasting mean square errors are particularly low (meaning attractor skeleton reconstructed with MSSA model fits original unemployment series quite well) for industrial production of durable consumer goods (CD), stocks of consumer durable goods (CDS), consumer price index (CPI), central bank discount rate (DR), EU industrial production (EU) and nominal net wage (NNW). Time series (variables) we identify as statistically significant affect unemployment trajectory path both in the short and the long run. Evidently, there is a strong Granger causality between them and the unemployment. Accordingly, we conclude that identified variables affect unemployment causing a shift (deviation) in the unemployment equilibrium trajectory when shocks do occur. No Granger causality is found for industrial production of intermediate goods, and weak Granger causality exists between unemployment and industrial production of consumer durable goods, industrial production of non-durable consumer goods. Spectral Granger causality in relation to standard (linear) Granger causality is quite robust, low noise level in the analysis (noise is removed using MSSA), causality is not previously fixed, test statistics not sensitive to model deviations. Further discussions on advantages of spectral Granger causality analysis over standard linear Granger causality can be found in the research of (Hassani et al., 2010; 2009; 2013a; 2013b; Patterson et al., 2011). By using multivariate series in forecasting unemployment dynamics in Croatia we can significantly improve forecasting accuracy in relation to the univariate SSA forecasting of unemployment.

Overall Granger causality test results show the existence of Granger causality between unemployment dynamics and time series we have used for the multivariate forecasting (MSSA model). Including considered multivariate series in attempt to understand non-linear and complex unemployment behaviour in Croatia is thus essential.

Using all identified oscillatory modes gives us a very good fit of the dynamic behaviour in the unemployment as it is visible from figure 3.

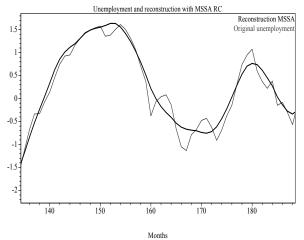

Figure 3. Unemployment and reconstruction with MSSA model RC

Source: Author's calculation

Robustness of our MSSA model is checked by doing insample and out-of-sample test. In sample test displayed in the figure above show MSSA model with selected RC pass the in-sample test (RMSE and RRMSE values) capturing local variance and co-movements important for understanding unemployment dynamic behaviour. We also check the MSSA model with the out-of-sample test forecasting unemployment using our MSSA model.

RMSE, RRMSE forecast error values for a 12 step ahead forecasting for unemployment shows a high accuracy of the forecast compared to the actual unemployment data. Forecast errors are small with forecast values close to the real data. Forecast accuracy of our MSSA model is quite remarkable with identified limit cycles capturing 76 % of the unemployment dynamic behaviour. Forecasting accuracy remains quite high even for a 24 step ahead forecast. After a 24 step ahead forecast, forecasting accuracy drops with MSSA model failing to capture the second cycle in the unemployment dynamics that reappeared in 2012. Our MSSA model fails to capture out-of-sample a 36 step ahead forecast's fluctuations registered in the unemployment behaviour during 2012 well capturing the dynamics in 2013. This could be due to other factors behind the fluctuations that our model did not capture using 88 time series variables, i.e. the remaining unexplained 24 % of fluctuations in the unemployment over the 1998–2013 period. More likely, since the MSSA model capture extremely well the period from 1998-2012, large transitory shocks (seasonal effects) in 2012 drove unemployment away from its limits cycles and identified attractors. One possible explanation could be the increasing seasonal effects from the tourism with the tourism sector growing and capturing a larger share of aggregate output with the steady decline of manufacturing share (advancing Croatian disease).

Finally, empirical results of the built MSSA model including in-sample and out-of-sample test show that multivariate singular spectrum analysis can explain most of the dynamic behaviour in the unemployment series. Our MSSA model captures 76 % of the total variance in the unemployment lifting the constraints (short time series, background noise, normality, stationarity and non-linearity) that other modelling technique fail to overcome.

Conclusion

Unemployment in Croatia shows a pattern of a complex system i.e. non-linearity, long memory and persistence -'partial Hysteresis'. Modelling unemployment, therefore, demands a complex model including all above variables. Research on unemployment in Croatia range from one assuming unemployment to be I(0) and others to be I(1). This paper offer an evidence on unemployment that is being fractionally integrated, i.e. non-stationary and with long memory in the conditional mean, variance. Thus unemployment series possess dual memory, both in mean and variance and this must be considered when modelling unemployment. Unemployment series in level is close to random walk but still not posses all properties to be declared as a random walk (Hysteresis). Empirical evidence offered in this study, therefore, calls for investigating what we call "partial Hysteresis" with unemployment having some properties of the random walk (non-stationarity) as well as of stationary series (mean reversion). Because of the evidence of fractional integration in the unemployment, stationarity and non-linearity issues (background noise) an multivariate singular spectrum model (MSSA) for modelling unemployment in Croatia is presented in this paper. Developed MSSA model offers a very good fit of the unemployment series explaining 76 % of the total variance in the unemployment series over the 1998-2013 period. From a pool of 88 variables under investigation 21 time series were selected as statistically important in explaining unemployment dynamic behaviour. Considered time series has passed all statistical testing (red noise Monte Carlo test, spectral Granger causality test, Diebold-Mariano test) fitting unemployment data in Croatia quite remarkably.

Using developed MSSA model, this paper presents empirical findings being significant both to the body of literature in economics and policy makers (having practical policy implications for the successful unemployment management). Unemployment in Croatia is caused by continuously shifting natural rate of unemployment and 'partial hysteresis'. A wide unemployment gap is evidenced. This is a consequence of both structural and cyclical component of unemployment. Macro mismanagement particularly present during the first decade of transition (1990–2000) led to a sharp increase in the natural rate of unemployment in Croatia. This sharp rise was the result of an inefficient privatization, war damages, building anemic labour market (job creation and destruction rates, job finding and separation rates, job turnover, labour mismatch) real economy sector oriented to simple reproduction cycles, insufficient capital funds and poor state support for building SME's, low rate of absorption from public to private sector during privatization, inadequate (too heavy) monetary anchors, hidden unemployment. During this period

natural rate of unemployment increased from 3 % to 5 % in 2001. Therefore, empirical results show structural (permanent) unemployment components led natural unemployment rate and thus unemployment dynamics during the 1990-2001 period. After 2001, the natural rate of unemployment becomes sluggish driven by a small cyclical component of unemple 2002-20 this per destruct no gap l remaine seasona conditio unempl dynami dropped unempl in 200 Unemp! increase cyclical demand market, product targetin particula in the unempl determi in the p cycles t develop cycle.
